Expression Tree Creation Algorithm

Notes:

- You don't need to memorize this for the final, but you should understand how it works.
- Reaching the end of the input is considered to be the lowest-precedence operator by this algorithm
- This algorithm employs two stacks, one for operators and one for references to expression subtrees (which are really just operands that have yet to be evaluated).
- This algorithm doesn't know how to handle parentheses or unary operators. It's not difficult to add those features, but this algorithm includes enough to build binary trees, which is the most important part.

```
1  initialize next_symbol to any legal operator or operand
2
3  while next_symbol is not end-of-the-input
4
5      read the next_symbol
6
7      if next_symbol is an operand
8
9          create an operand node
10         place next_symbol in the node
11         push a reference to the node on the operand stack
12
13     else if the operator stack is empty,
14             or top(operator stack) has lower precedence than next_symbol
15
16         push next_symbol onto the operator stack
17
18     else
19
20         while the operator stack is not empty AND top(operator stack) has
21         precedence higher than or equal to next_symbol
22
23             pop the top operator from the operator stack
24             create a new operator node
25             place the popped operator into the node
26
27             pop the top reference from the operand stack
28             store that reference into the node's right child reference field
29
30             pop the top reference from the operand stack
31             store that reference into the node's left child reference field
32
33             push a reference to the node on the operand stack
34
35         end while
36
37         push next_symbol onto the operator stack
38
39     end if
40
41 end while
```
