C I/O

UNIX I/O

- Every UNIX process (running program) has three standard I/O connections to the outside world:

  stdin: Standard in. When the user types stuff to the terminal, it appears on the stdin I/O connection.

  stdout: Standard out. When the program prints something to the stdout connection it typically shows up on the terminal.

  stderr: Standard error. The program prints its error messages to stderr, which also typically shows up on the terminal.

Slide 18–1

Redirecting I/O connections

- Typically these are connected to the terminal so the user can see what the program prints, and type stuff into the program.
- The user can change (redirect) the standard I/O connections for a program before it runs, so that they are not connected to the terminal. Instead, they can be connected to a file, or even another program.
- Redirecting the standard I/O connections is handled by the shell, the UNIX program that gives you the prompt at which you type commands.

Slide 18–2

Redirecting I/O connections...

- Different shells have different syntax for redirection.
- The C-shell (csh) uses the following:

```
$ a.out > out
```

  This command causes the shell to run the program a.out, but to connect the program's stdout to the file out. Everything the program prints to stdout is written to the file. If the file doesn't exist, it is created, and if it does exist, its contents are overwritten. stdin and stderr remain connected to the terminal.

Slide 18–3

Redirecting I/O connections...

- Both `stdout` and `stderr` are written to the file `out`.

```
$ a.out >& out
```

- stdin is connected to the file `in`. Instead of reading what the user types, the program reads it from the file `in`. It is an error if `in` doesn't exist.

```
$ a.out < in
```

- `stdin`, `stdout`, and `stderr` are all redirected. `stdin` is connected to the file `in`, `stdout` and `stderr` to the file `out`.

```
$ a.out < in >& out
```

Slide 18–4

Redirecting I/O connections...

- Redirection can also be done to another program. This creates a pipeline, because the stdout of one program is connected to the stdin of another:

```
$ grep Heap heap.c | wc
```

The `stdout` of the `grep` program is connected to the `stdin` of the `wc` program. This pipeline tells you how many times the string `"Heap"` appears in `heap.c`.

Slide 18–5

`int printf(char *fmt, ...)`

- Probably the most common way of producing output from a C program is the `printf` routine, which prints a formatted string to `stdout`. printf is very complicated – I'll just cover the core functionality here; see the man page for more details.
- The declaration for `printf` (and all these I/O routines) is in `stdio.h`. Include it via:

```
#include <stdio.h>
```

Slide 18–6

printf...

- The `fmt` parameter is the format string. "Ordinary" characters in the string are copied to `stdout` directly.
- A backslash '\' indicates that it and the next character form a special character:
  1. \n – newline
  2. \t – tab
  3. \r – carriage return
  4. \\ – backslash character
  5. \" – double-quote
  6. \' – single-quote

Slide 18–7

printf...

- A percent sign '`%`' indicates the start of a conversion specification. A conversion specification causes `printf` to convert its next parameter to an ASCII string and print it:
  1. `%d` – signed decimal integer
  2. `%u` – unsigned decimal integer
  3. `%x` – hexadecimal integer (characters in lower-case)
  4. `%X` – hexadecimal integer (characters in upper-case)
  5. `%s` – null-terminated string
  6. `%f` – floating-point number
  7. `%p` – pointer
  8. `%%` – percent sign (doesn't consume parameter)

Slide 18–8

printf...

- `printf` has a variable number of parameters, as specified by the format string. It returns the number of characters printed.

```
char  *name = "Fred";
int    value = 17;
printf("Name = %s, value = %d\n", name, value);
  Name = Fred, value = 17
printf("Name = \"%s\", value = %d\n", name, value);
  Name = "Fred", value = 17
printf("%s\n", "Hello World");
  Hello World
printf("Value = 0x%x\n", value);
  Value = 0x11
```

Slide 18–9

Conversion specifications

- Conversion specifications can be very complicated, and in general have the following elements after the '`%`', in order:

%	*flags*	*width*	*.prec*	*size*	*conv*

size Size modifier. Used to convert longs and shorts.

.prec Precision (period followed by an optional decimal). Number of digits to the right of the decimal point, or number of characters from string.

Slide 18–10

flags Zero or more flag characters (-,+,0,#, or space):

- The converted value is left-justified within the field.

+ Positive numbers are preceded by '+'.

0 Numbers are padded to the left with '0' instead of spaces.

space A space is put to the left of numbers without signs.

Alternate form of conversion

width Minimum field width (a decimal number). Causes output to be padded to this many characters.

Slide 18–11

Format String Examples

- Examples of printing 10 with different format strings:

Fmt	Output
"|%d|"	|10|
"|%4d|"	| 10|
"|%4.2d|"	| 10|
"|%04d|"	|0010|
"|%-04d|"	|10 |
"|% d|"	| 10|
"|%+d|"	|+10|

Slide 18–12

int scanf(char *fmt, ...)

- Reads characters from `stdin`, formats them according to the conversion specifiers in the format string, and stores them in the pointers passed as parameters. Returns the number of conversions performed.
- The `fmt` string has the same format as for `printf`, with a few exceptions:
  1. Whitespace matches any amount of whitespace in the input, including none.
  2. `[ ]` matches a sequence of characters from those between the brackets.

Slide 18–13

scanf...

- Always check the return value from `scanf` to verify that the input was converted properly.
- Example:

```
char    name[21];
int     value;
n = scanf(" %20s", name);
n = scanf(" %d", &value);
```

Slide 18–14

fprintf,fscanf

```
int fprintf(FILE *stream, char *fmt, ...);
int fscanf(FILE *stream, char *fmt, ...);
```

- `fprintf` and `fscanf` work like `printf` and `scanf`, except you can specify which I/O connection (file) to use. What I've been calling an "I/O connection" is represented in UNIX by a pointer to a structure of type `FILE`. This is often called a stream. `stdin`, `stdout`, and `stderr` are pre-defined streams.

```
fprintf(stderr, "Something went wrong!\n");
fscanf(stdin, " %d", &value);
```

Slide 18–15

fopen,fclose

```
FILE     *fopen(char *name, char *mode);
int      fclose(FILE *stream);
```

- `fopen` and `fclose` are used to open and close new I/O connections. `name` is the name of the file to open, `mode` is how to open it: `"r"`=read-only, `"w"`=write-only, `"rw"`=read/write.

```
FILE *file;
file = fopen("/tmp/foo", "rw");
(void) fprintf(file, "Hello World\n");
(void) fclose(file);
```

sprintf,sscanf

```
int sprintf(char *string, char *fmt, ...);
int sscanf(char *string, char *fmt, ...);
```

- `sprintf` and `sscanf` work exactly like `printf` and `scanf`, except they read write to another string:

```
char               buffer[100];
sprintf(buffer, "Value = %d", value);
sscanf(buffer, "Value = %d", &value);
```

Misc.

- There are many I/O routines in the C library. Refer to the man pages or a reference manual. Here are a few examples:

fread, fwrite – read and write arrays of data

fgetc, getc – reads the next character from a stream

fgets, gets – reads a string from a stream (up to newline)

fputc,putc – writes a character to a stream

fputs, puts – writes a string to a stream

errno

- The global variable `errno` is used by many C library routines to return error codes. The standard error codes are defined in `/usr/include/errno.h`.
- The easiest way to deal with `errno` is to use the `perror` function to print a reasonable message to `stderr`:

```
stream = fopen("foo", "r");
if (stream == NULL) {
    perror("Unable to open file");
}
```

errno

- If `fopen` fails because `"foo"` doesn't exist, the output might be:

```
Unable to open file: file not found
```

- The function `strerror` returns the error message associated with an error code.
